Machine Learning Engineer Nanodegree

Model Evaluation & Validation

Project 1: Predicting Boston Housing Prices

Welcome to the first project of the Machine Learning Engineer Nanodegree! In this notebook, some template code has already been written. You will need to implement additional functionality to successfully answer all of the questions for this project. Unless it is requested, do not modify any of the code that has already been included. In this template code, there are four sections which you must complete to successfully produce a prediction with your model. Each section where you will write code is preceded by a **STEP X** header with comments describing what must be done. Please read the instructions carefully!

In addition to implementing code, there will be questions that you must answer that relate to the project and your implementation. Each section where you will answer a question is preceded by a **QUESTION X** header. Be sure that you have carefully read each question and provide thorough answers in the text boxes that begin with "**Answer:**". Your project submission will be evaluated based on your answers to each of the questions.

A description of the dataset can be found <u>here (https://archive.ics.uci.edu/ml/datasets/Housing)</u>, which is provided by the **UCI Machine Learning Repository**.

Getting Started

To familiarize yourself with an iPython Notebook, **try double clicking on this cell**. You will notice that the text changes so that all the formatting is removed. This allows you to make edits to the block of text you see here. This block of text (and mostly anything that's not code) is written using Markdown (http://daringfireball.net/projects/markdown/syntax), which is a way to format text using headers, links, italics, and many other options! Whether you're editing a Markdown text block or a code block (like the one below), you can use the keyboard shortcut **Shift + Enter** or **Shift + Return** to execute the code or text block. In this case, it will show the formatted text.

Let's start by setting up some code we will need to get the rest of the project up and running. Use the keyboard shortcut mentioned above on the following code block to execute it. Alternatively, depending on your iPython Notebook program, you can press the **Play** button in the hotbar. You'll know the code block executes successfully if the message "Boston Housing dataset loaded successfully!" is printed.

```
In [1]: # Importing a few necessary libraries
        import numpy as np
        import matplotlib.pyplot as pl
        from sklearn import datasets
        from sklearn.tree import DecisionTreeRegressor
        # Make matplotlib show our plots inline (nicely formatted in the notebook)
        %matplotlib inline
        # Create our client's feature set for which we will be predicting a selling p
        CLIENT_FEATURES = [[11.95, 0.00, 18.100, 0, 0.6590, 5.6090, 90.00, 1.385, 24,
         680.0, 20.20, 332.09, 12.13]]
        # Load the Boston Housing dataset into the city_data variable
        city_data = datasets.load_boston()
        # Initialize the housing prices and housing features
        housing_prices = city_data.target
        housing_features = city_data.data
        print "Boston Housing dataset loaded successfully!"
```

Boston Housing dataset loaded successfully!

Statistical Analysis and Data Exploration

In this first section of the project, you will quickly investigate a few basic statistics about the dataset you are working with. In addition, you'll look at the client's feature set in CLIENT_FEATURES and see how this particular sample relates to the features of the dataset. Familiarizing yourself with the data through an explorative process is a fundamental practice to help you better understand your results.

Step 1

In the code block below, use the imported numpy library to calculate the requested statistics. You will need to replace each None you find with the appropriate numpy coding for the proper statistic to be printed. Be sure to execute the code block each time to test if your implementation is working successfully. The print statements will show the statistics you calculate!

```
In [2]: # Number of houses in the dataset
        total_houses = housing_prices.shape[0]
        # Number of features in the dataset
        total_features = housing_features.shape[1]
        # Minimum housing value in the dataset
        minimum_price = np.min(housing_prices)
        # Maximum housing value in the dataset
        maximum_price = np.max(housing_prices)
        # Mean house value of the dataset
        mean_price = np.mean(housing_prices)
        # Median house value of the dataset
        median_price = np.median(housing_prices)
        # Standard deviation of housing values of the dataset
        std_dev = np.std(housing_prices)
        # Show the calculated statistics
        print "Boston Housing dataset statistics (in $1000's):\n"
        print "Total number of houses:", total_houses
        print "Total number of features:", total_features
        print "Minimum house price:", minimum_price
        print "Maximum house price:", maximum_price
        print "Mean house price: {0:.3f}".format(mean_price)
        print "Median house price:", median_price
        print "Standard deviation of house price: {0:.3f}".format(std_dev)
        Boston Housing dataset statistics (in $1000's):
        Total number of houses: 506
        Total number of features: 13
        Minimum house price: 5.0
        Maximum house price: 50.0
        Mean house price: 22.533
        Median house price: 21.2
```

As a reminder, you can view a description of the Boston Housing dataset here (https://archive.ics.uci.edu/ml/datasets//here to the Boston Housing), where you can find the different features under **Attribute Information**. The MEDV attribute relates to the values stored in our housing_prices variable, so we do not consider that a feature of the data.

Of the features available for each data point, choose three that you feel are significant and give a brief description for each of what they measure.

Remember, you can **double click the text box below** to add your answer!

Standard deviation of house price: 9.188

I feel like the variables CRIM, DIS and RAD are the most significant in this dataset. They measure the per capita crime rate by town, the weighted distances to five Boston employment centres and the index of accessibility to radial highways.

Question 2

Using your client's feature set CLIENT_FEATURES, which values correspond with the features you've chosen above? **Hint:** Run the code block below to see the client's data.

```
In [3]: print CLIENT_FEATURES

[[11.95, 0.0, 18.1, 0, 0.659, 5.609, 90.0, 1.385, 24, 680.0, 20.2, 332.09,
12.13]]
```

In this client's feature set, 11.95 corresponds to the per capita crime rate, 1.385 is the weighted distances to five Boston employment centres and 24 is the index of accessibility to radial highways.

Evaluating Model Performance

In this second section of the project, you will begin to develop the tools necessary for a model to make a prediction. Being able to accurately evaluate each model's performance through the use of these tools helps to greatly reinforce the confidence in your predictions.

Step 2

In the code block below, you will need to implement code so that the shuffle_split_data function does the following:

- Randomly shuffle the input data x and target labels (housing values) y.
- Split the data into training and testing subsets, holding 30% of the data for testing.

If you use any functions not already accessible from the imported libraries above, remember to include your import statement below as well!

Ensure that you have executed the code block once you are done. You'll know if the shuffle_split_data function is working if the statement "Successfully shuffled and split the data!" is printed.

```
In [4]:
        # Put any import statements you need for this code block here
        from sklearn.cross_validation import train_test_split
        def shuffle_split_data(X, y):
            """ Shuffles and splits data into 70% training and 30% testing subsets,
                then returns the training and testing subsets. """
            # Shuffle and split the data
            X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.30,
         random_state=42)
            #X_train = None
            #y_train = None
            \#X\_test = None
            #y\_test = None
            # Return the training and testing data subsets
            return X_train, y_train, X_test, y_test
        # Test shuffle_split_data
            X_train, y_train, X_test, y_test = shuffle_split_data(housing_features, h
        ousing_prices)
            print "Successfully shuffled and split the data!"
        except:
            print "Something went wrong with shuffling and splitting the data."
```

Successfully shuffled and split the data!

Why do we split the data into training and testing subsets for our model?

We do split the data into training and testing because evaluating the performance of a classifier or a regression on the same data used to train an algorithm usually leads to an optimistically biased assessment. The simplest strategy for correcting the optimism bias is to hold out a portion of the development data for assessment.

Step 3

In the code block below, you will need to implement code so that the performance_metric function does the following:

Perform a total error calculation between the true values of the y labels y_true and the predicted values of the
y labels y_predict.

You will need to first choose an appropriate performance metric for this problem. See the sklearn metrics documentation (http://scikit-learn.org/stable/modules/classes.html#sklearn-metrics-metrics) to view a list of available metric functions.

Hint: Look at the question below to see a list of the metrics that were covered in the supporting course for this project.

Once you have determined which metric you will use, remember to include the necessary import statement as well! Ensure that you have executed the code block once you are done. You'll know if the performance_metric function is working if the statement "Successfully performed a metric calculation!" is printed.

```
In [5]: # Put any import statements you need for this code block here
from sklearn.metrics import mean_squared_error

def performance_metric(y_true, y_predict):
    """ Calculates and returns the total error between true and predicted val
    ues
        based on a performance metric chosen by the student. """

        error = mean_squared_error(y_true, y_predict)
        return error

# Test performance_metric
try:
        total_error = performance_metric(y_train, y_train)
        print "Successfully performed a metric calculation!"
except:
        print "Something went wrong with performing a metric calculation."
```

Successfully performed a metric calculation!

Question 4

Which performance metric below did you find was most appropriate for predicting housing prices and analyzing the total error. Why?

- Accuracy
- Precision
- Recall
- F1 Score
- Mean Squared Error (MSE)
- Mean Absolute Error (MAE)

I find that the Mean Squared Error is the most appropriate performance metric for predicting housing prices because the response is quantitative. Accuracy, Precision, recall and F1 score are metrics used when predicting a qualitative response variable. MSE has nice mathematical properties which makes it easier to compute the gradient. MAE requires more complicated tools such as linear programming to compute the gradient. Because of the square, large errors have relatively greater influence on MSE than do the smaller error. Therefore, MAE is more robust to outliers since it does not make use of square. On the other hand, MSE is more useful if we are concerned about large errors whose consequences are much bigger than equivalent smaller ones.

Step 4 (Final Step)

In the code block below, you will need to implement code so that the fit_model function does the following:

- Create a scoring function using the same performance metric as in **Step 2**. See the <u>sklearn make scorer</u> documentation (http://scikit-learn.org/stable/modules/generated/sklearn.metrics.make_scorer.html).
- Build a GridSearchCV object using regressor, parameters, and scoring_function. See the <u>sklearn</u> documentation on GridSearchCV (http://scikit-learn.org/stable/modules/generated/sklearn.grid_search.GridSearchCV.html).

When building the scoring function and GridSearchCV object, be sure that you read the parameters documentation thoroughly. It is not always the case that a default parameter for a function is the appropriate setting for the problem you are working on.

Since you are using sklearn functions, remember to include the necessary import statements below as well!

Ensure that you have executed the code block once you are done. You'll know if the fit_model function is working if the statement "Successfully fit a model to the data!" is printed.

```
In [6]: # Put any import statements you need for this code block
        from sklearn.metrics import fbeta_score, make_scorer
        from sklearn.grid_search import GridSearchCV
        def fit_model(X, y):
            """ Tunes a decision tree regressor model using GridSearchCV on the input
         data X
                and target labels y and returns this optimal model. """
            # Create a decision tree regressor object
            regressor = DecisionTreeRegressor()
            # Set up the parameters we wish to tune
            parameters = {'max_depth':(1,2,3,4,5,6,7,8,9,10)}
            # Make an appropriate scoring function
            scoring_function = make_scorer(mean_squared_error,greater_is_better=False
        )
            # Make the GridSearchCV object
            reg = GridSearchCV(regressor, parameters,scoring = scoring_function)
            # Fit the learner to the data to obtain the optimal model with tuned para
        meters
            reg.fit(X, y)
            # Return the optimal model
            return reg
        # Test fit_model on entire dataset
            reg = fit_model(housing_features, housing_prices)
            print "Successfully fit a model!"
        except:
            print "Something went wrong with fitting a model."
```

Successfully fit a model!

Question 5

What is the grid search algorithm and when is it applicable?

The Grid search algorithm is a way of systematically working through multiple combinations of parameter tunes, cross-validating as it goes to determine which tune gives the best performance. The Grid search algorithm picks out a grid of hyperparameter values, evaluates every one of them, and returns the winner. Grid search is most appropriate when function evaluations are cheap or the number of parameters is small.

Question 6

What is cross-validation, and how is it performed on a model? Why would cross-validation be helpful when using grid search?

Cross-Validation is a model validation technique for assessing how the results of a statistical analysis will generalize to an independent data set. It is mainly used in settings where the goal is prediction, and one wants to estimate how accurately a predictive model will perform in practice. It is performed by removing some data if data are not scarce, before training begins. Then when training is done, the data that was removed can be used to test the performance of the learned model on new data. When combined with grid search, cross-validation is used to evaluate every possible combination of a set of parameter values that we want to try on a given model.

Checkpoint!

You have now successfully completed your last code implementation section. Pat yourself on the back! All of your functions written above will be executed in the remaining sections below, and questions will be asked about various results for you to analyze. To prepare the **Analysis** and **Prediction** sections, you will need to intialize the two functions below. Remember, there's no need to implement any more code, so sit back and execute the code blocks! Some code comments are provided if you find yourself interested in the functionality.

```
In [9]: def learning_curves(X_train, y_train, X_test, y_test):
            """ Calculates the performance of several models with varying sizes of tr
        aining data.
                The learning and testing error rates for each model are then plotted.
            print "Creating learning curve graphs for max_depths of 1, 3, 6, and 10.
            # Create the figure window
            fig = pl.figure(figsize=(10,8))
            # We will vary the training set size so that we have 50 different sizes
            sizes = np.round(np.linspace(1, len(X_train), 50))
            train_err = np.zeros(len(sizes))
            test_err = np.zeros(len(sizes))
            # Create four different models based on max_depth
            for k, depth in enumerate([1,3,6,10]):
                for i, s in enumerate(sizes):
                    # Setup a decision tree regressor so that it learns a tree with m
        ax\_depth = depth
                    regressor = DecisionTreeRegressor(max_depth = depth)
                    # Fit the learner to the training data
                    regressor.fit(X_train[:s], y_train[:s])
                    # Find the performance on the training set
                    train_err[i] = performance_metric(y_train[:s], regressor.predict(
        X_train[:s]))
                    # Find the performance on the testing set
                    test_err[i] = performance_metric(y_test, regressor.predict(X_test
        ) )
                # Subplot the learning curve graph
                ax = fig.add\_subplot(2, 2, k+1)
                ax.plot(sizes, test_err, lw = 2, label = 'Testing Error')
                ax.plot(sizes, train_err, lw = 2, label = 'Training Error')
                ax.legend()
                ax.set_title('max_depth = %s'%(depth))
                ax.set_xlabel('Number of Data Points in Training Set')
                ax.set_ylabel('Total Error')
                ax.set_xlim([0, len(X_train)])
            # Visual aesthetics
            fig.suptitle('Decision Tree Regressor Learning Performances', fontsize=18
        y=1.03
            fig.tight_layout()
            fig.show()
```

```
In [10]: def model_complexity(X_train, y_train, X_test, y_test):
             """ Calculates the performance of the model as model complexity increases
                 The learning and testing errors rates are then plotted. """
             print "Creating a model complexity graph. . . "
             # We will vary the max_depth of a decision tree model from 1 to 14
             max_depth = np.arange(1, 14)
             train_err = np.zeros(len(max_depth))
             test_err = np.zeros(len(max_depth))
             for i, d in enumerate(max_depth):

          d
                 regressor = DecisionTreeRegressor(max_depth = d)
                 # Fit the learner to the training data
                 regressor.fit(X_train, y_train)
                 # Find the performance on the training set
                 train_err[i] = performance_metric(y_train, regressor.predict(X_train)
         )
                 # Find the performance on the testing set
                 test_err[i] = performance_metric(y_test, regressor.predict(X_test))
             # Plot the model complexity graph
             pl.figure(figsize=(7, 5))
             pl.title('Decision Tree Regressor Complexity Performance')
             pl.plot(max_depth, test_err, lw=2, label = 'Testing Error')
             pl.plot(max_depth, train_err, lw=2, label = 'Training Error')
             pl.legend()
             pl.xlabel('Maximum Depth')
             pl.ylabel('Total Error')
             pl.show()
```

Analyzing Model Performance

In this third section of the project, you'll take a look at several models' learning and testing error rates on various subsets of training data. Additionally, you'll investigate one particular algorithm with an increasing max_depth parameter on the full training set to observe how model complexity affects learning and testing errors. Graphing your model's performance based on varying criteria can be beneficial in the analysis process, such as visualizing behavior that may not have been apparent from the results alone.

```
In [11]: learning_curves(X_train, y_train, X_test, y_test)
```

Creating learning curve graphs for max_depths of 1, 3, 6, and 10. . .

Question 7

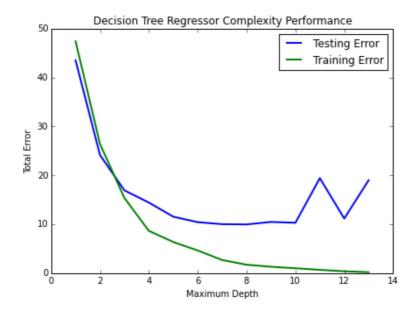

Choose one of the learning curve graphs that are created above. What is the max depth for the chosen model? As the size of the training set increases, what happens to the training error? What happens to the testing error?

The max depth for the chosen model is 10. As the size of the training set increases, the training error rate increases slightly while the testing error decreases suddenly from around 130 to 30 and remains at this level whatever dimensions are added to the model. The training error increases slightly because as we get more training observations, it becomes harder for the model to fit the training data, so the training error goes up. On the other hand, if we have more data the model becomes better at generalizing, so the testing error goes down.

Look at the learning curve graphs for the model with a max depth of 1 and a max depth of 10. When the model is using the full training set, does it suffer from high bias or high variance when the max depth is 1? What about when the max depth is 10?

The training and testing errors in the model with max depth 1 converge and are quite high when the model is using the full training set. This model has systematic high errors and that means it is high biased. When the model is using the full training set and the max depth is 10, there is a large variance gap between the training and the test errors. It has a high variance. For the max depth 10, the training error is close to zero. That's means the algorithm is completely fitting the data and we will high probability to overfit.

```
In [12]: model_complexity(X_train, y_train, X_test, y_test)
Creating a model complexity graph. . .
```

Question 9

From the model complexity graph above, describe the training and testing errors as the max depth increases. Based on your interpretation of the graph, which max depth results in a model that best generalizes the dataset? Why?

The complexity graph above indicates that the bias is reduced to almost zero for maximum depth greater than 12, but the variance term and, consequently, the generalization performance is not reduced further, staying approximatelly constant after a maximum depth of 6 or 7 is reached. A maximum depth between 4 and 7 generalises the dataset the best. It seems the model reaches its limit at that maximum depth because the training error and the testing error seem to be very close.

Model Prediction

In this final section of the project, you will make a prediction on the client's feature set using an optimized model from fit_model. To answer the following questions, it is recommended that you run the code blocks several times and use the median or mean value of the results.

Using grid search on the entire dataset, what is the optimal max_depth parameter for your model? How does this result compare to your initial intuition?

Hint: Run the code block below to see the max depth produced by your optimized model.

```
In [13]: print "Final model optimal parameters:", reg.best_params_
Final model optimal parameters: {'max_depth': 4}
```

The optimal max depth for the model is 7. This exactly matches my initial intuition, the interval between 4 and 7...

Question 11

With your parameter-tuned model, what is the best selling price for your client's home? How does this selling price compare to the basic statistics you calculated on the dataset?

Hint: Run the code block below to have your parameter-tuned model make a prediction on the client's home.

```
In [14]: sale_price = reg.predict(CLIENT_FEATURES)
    print "Predicted value of client's home: {0:.3f}".format(sale_price[0])
    Predicted value of client's home: 21.630
```

The best selling price for the client's home is 21.630, below the mean house price is nearly equivalent to the median house price.

Question 12 (Final Question):

In a few sentences, discuss whether you would use this model or not to predict the selling price of future clients' homes in the Greater Boston area.

We can use a multivariate regression algorithm to predict the selling price. Multivariate regression is intended for models where we want to estimate E[Y|X], where X is a set of predictors and the residuals from the model are continuous and Gaussian with mean 0. However, I would use the decision tree model to predict the selling price of future clients' homes in the greater Boston area because it is popular in the prediction of housing prices litterature, it is simple to understand and interpret and it requires little data preparation. cf: https://en.wikipedia.org/wiki/Decision_tree_learning)

(https://en.wikipedia.org/wiki/Decision_tree_learning)
